A new scheme for spontaneous formation of hexagonal optical patterns in photorefractive crystals with dominant reflection gratings and a single pump wave is proposed and realized experimentally. It is shown theoretically that spontaneous hexagon formation results from random small-angle scattering of the pump wave inside the crystal. The threshold of spontaneous hexagon formation is found. © 1999 Optical Society of America

The interaction of counterpropagating optical waves in nonlinear media often results in transverse instabilities and in the formation of regular spatial structures, mostly with hexagonal symmetry. Hexagonal patterns have been observed in a wide variety of materials, including atomic vapors, liquid crystals, and photorefractive crystals.¹ Counterpropagating beams interact by means of diffraction on the self-induced reflection or transmission gratings of a nonlinear medium.^{2,3} The threshold of instability and the angular scale of the patterns generated have depended on whether the second pump was produced externally³⁻⁶ or arose from the first beam by reflection from a feedback mirror placed outside the nonlinear medium.² Two counterpropagating pump waves were essential in all those experiments as well as in theoretical calculations of transverse instabilities. Here we propose, for the first time to our knowledge, and have realized experimentally a new scheme for pattern generation in photorefractive crystals with dominant reflection gratings. The chief unique characteristic of this scheme is the presence of only one pump wave, which, as is shown below, lends unusual properties to the system.

A schematic of the setup is shown in Fig. 1. Coherent laser beam F_0 is directed into photorefractive crystal C, where recording of reflection gratings of the diffusion type⁷ is possible. The output surface of the crystal is imaged by lenses L_1 and L_2 , which form a $4f$ system upon mirror M. Circular slit D is placed in the common focal plane of these lenses. This circular slit cuts off all angular components of laser radiation except the range $(\theta, \theta + \delta\theta)$, where $\theta \ll 1$ and $\delta\theta/\theta \ll 1$. As a result, mirror M reflects only side-band beams with a transverse wave vectors \mathbf{k}_\perp that lie upon ring $|\mathbf{k}_\perp| \approx \theta k_0$, where k_0 is the wave vector of the pump beam.

We performed the experiment by using the principal configuration shown in Fig. 1. A crystal of $\text{KNbO}_3:\text{Fe}$ (0.5 wt.%) measuring $l = 5.2$ mm along the c axis was illuminated by a 35-mW laser beam at $\lambda = 632.8$ nm

focused onto a spot with a Gaussian diameter of ~ 0.3 mm. The light was polarized parallel to the crystal a axis to take advantage of the r_{13} electro-optic coefficient. The crystal was slightly tilted ($\approx 10^\circ$) to avoid the influence of the beam reflected from the back surface of the crystal. The circular slit cut the pump beam off and passed only a part of the scattered radiation. This scattered light is due to the scattering of the pump on the crystal inhomogeneities and represents a speckle field in the plane of filtering. The width of the circular slit was chosen to coincide approximately with a transverse size of a speckle spot. The crystal was oriented such that the scattered light reflected from mirror M was amplified by pump F_0 . A part of the output radiation reflected by a beam splitter (not shown in Fig. 1) was used for recording near- and far-field pictures and the time dependence of the generated radiation.

The experimental results are presented in Figs. 2 and 3. Figure 2 shows images of near-field patterns at the input surface of the crystal (right) and far-field patterns (left) for two values of the circular slit diameter. Note that increasing the width of the circular slit to 3–4 speckle-spot size destroys the hexagonal symmetry of the generated radiation.

Typical temporal dynamics of the generated radiation for two values of the coupling constant are shown in Fig. 3. If the system is below the threshold for spontaneous hexagon formation (curve 1), the power of the generated wave tends to a low plateau determined by

Fig. 1. Schematic of the setup for hexagon formation. Abbreviations are defined in text.

Fig. 3. Time dynamics of the generated radiation.

the amplification of randomly scattered light passed through the filtering system. The intensity distribution in the far field has a speckled ring structure (inset in Fig. 3). Above that threshold the system settles first at a low plateau with a short time scale determined by the photorefractive relaxation time.⁷ Then the system tends to the upper plateau (curve 2) with a slow time scale determined by the supercriticality. At the upper plateau the power of generated light is approximately 30–40% of the pump wave power.

Here we show that spontaneous hexagon formation results from random small-angle forward scattering of the pump wave inside the crystal. This scattered wave is time independent, and, propagating in forward direction, it does not interact with the pump wave. But after passing through the filtering system it serves as a seed wave for hexagon formation. The intensity of this seed wave is extremely small (approximately $10^{-5...-6}$ with respect to the pump wave intensity) and determines the threshold of spontaneous hexagon formation.

Let two linearly polarized light waves $F \exp(in_0 k_0 z - i\omega_0 t)$ and $B \exp(-in_0 k_0 z - i\omega_0 t)$ counterpropagate in a photorefractive crystal. Here $F(\mathbf{r}_\perp, z, t)$ and $B(\mathbf{r}_\perp, z, t)$ are slowly varying complex amplitudes of waves; k_0 and ω_0 are their respective wave numbers and angular frequencies, n_0 is the refractive index of the crystal, and $\mathbf{r}_\perp = (x, y)$ is a transverse coordinate. The length of the crystal along the z axis is equal to l (see Fig. 1). Waves F and B can be written as

$$F = F_0 \left[\exp(-\alpha z) + \sum_{\mathbf{k}} \exp(i\mathbf{k}\mathbf{r}_\perp) F_k(z, t) \right],$$

$$B = F_0 \sum_{\mathbf{k}} \exp(i\mathbf{k}\mathbf{r}_\perp) B_k(z, t), \quad (1)$$

where $F_0 \exp(-\alpha z)$ is the pump amplitude, α is the linear absorption coefficient of the crystal, $\mathbf{k} = (k_x, k_y)$ is the transverse wave vector in the (x, y) plane (here and below we omit the subscript \perp in the wave-vector notation), and F_k and B_k are weak sideband amplitudes. Space-charge field $E(\mathbf{r}_\perp, z, t)$ can be written as follows⁸:

$$E(\mathbf{r}_\perp, z, t) = \exp(2in_0 k_0 z) \times \sum_{\mathbf{k}} \exp(i\mathbf{k}\mathbf{r}_\perp) E_{2k_0, \mathbf{k}}(z, t) + \text{c.c.} \quad (2)$$

Then, in a way similar to that described in Ref. 8 and taking into account only terms up to the second order of nonlinearity by amplitudes B_k and $E_{2k_0, \mathbf{k}}$, we get

$$\left(\frac{\partial}{\partial z} + ik_d + \alpha \right) F_k = i\gamma \sum_{\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}} E_{2k_0, \mathbf{k}_1} B_{\mathbf{k}_2},$$

$$\left(\frac{\partial}{\partial z} - ik_d - \alpha \right) B_k = -i\gamma^* \exp(-\alpha z) E_{2k_0, -\mathbf{k}}^*,$$

$$t_d \frac{\partial E_{2k_0, \mathbf{k}}}{\partial t} = -\exp(-2\alpha z) E_{2k_0, \mathbf{k}} + \exp(-\alpha z) B_k^*, \quad (3)$$

where $\gamma \equiv \gamma_r + i\gamma_i$ is the photorefractive coupling coefficient and t_d is the photorefractive relaxation time, which is inversely proportional to the pump intensity $k_d = k^2/2k_0 n_0$. In deriving Eqs. (3) we used the fact that amplitudes F_k are quadratic with respect to amplitudes B_k and $E_{2k_0, \mathbf{k}}$ because the linear terms on the right-hand side of the first equation of system (3) are absent. The result is the splitting of the last two of Eqs. (3) from the first one.

The filtering system selects from the scattered wave a small part that consists of a number of seed beams with transverse wave vectors lying in the Fourier plane on the ring $|\mathbf{k}| \approx \theta k_0$. Thus the boundary condition for the waves F_k and B_k can be written as

$$F_k(0) = 0, \quad B_k(l) = F_k(l) \exp(i\phi) r + B_k^{\text{seed}}, \quad (4)$$

where B_k^{seed} are the amplitudes of the seed beams, r is the amplitude reflection coefficient of the feedback mirror (we also include in this coefficient the losses on the crystal back surface), and ϕ is a phase shift of the sideband amplitudes as they propagate from the crystal back surface to the mirror and back. The value of B_k^{seed} is very small in the experiment ($|B_k^{\text{seed}}|^2 \sim 10^{-5...-6}$).

In a quadratic approximation, which it is natural to term a weakly nonlinear approximation, the intensities of the sidebands are nonzero only on the ring $|\mathbf{k}_\perp| \approx \theta k_0$. Then it follows from the condition of three-wave

interaction $\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}$ that the nonlinear terms on the right-hand sides of Eqs. (3) have a nonzero value only for the interaction of those sidebands having transverse wave vectors spaced by angular multiples of $\pi/3$. Six such vectors form a hexagon.⁸ It is important that in the weakly nonlinear approximation the different hexagons that lie upon the ring do not interact with one another. So in this approximation we can limit the analysis to only one hexagon.

Consider the simplest case, in which the amplitudes B_k^{seed} , F_k , B_k , and $E_{2k_0, k}$ do not depend on \mathbf{k} . Then the system of Eqs. (3) reduces in a steady state to

$$\begin{aligned} \left(\frac{\partial}{\partial z} + \alpha + ik_d\right)F_k &= 2i\gamma\exp(\alpha z)|B_k|^2, \\ \left(\frac{\partial}{\partial z} - \alpha - ik_d\right)B_k &= -i\gamma^*B_k. \end{aligned} \quad (5)$$

From Eqs. (5) and (4) we can get the intensity of the weakly nonlinear stationary solution:

$$|B_k(l)|^2 = \frac{1 - C_B^* - C_B \pm \sqrt{D}}{2|C|^2}, \quad (6)$$

where

$$\begin{aligned} C &= \frac{2i\gamma r \exp(i\phi + \alpha l)}{2\gamma_i - ik_d - 4\alpha} \{\exp[(2\gamma_i - ik_d - 4\alpha)l] - 1\}, \\ C_B &= CB_k^{\text{seed}*}, \quad D = (C_B + C_B^* - 1)^2 - 4|C_B|^2. \end{aligned} \quad (7)$$

This solution exists provided that $D \geq 0$, from which it follows that the seed intensity $|B_k^{\text{seed}}|^2$ must be less the threshold value $|B_k^{\text{thresh}}|^2$ given by

$$|B_k^{\text{thresh}}|^2 = \frac{1}{16|C|^2 \cos^4(\psi/2)}, \quad \psi = \arg(C_B). \quad (8)$$

The threshold of spontaneous hexagon formation depends on ψ and, as consequence, it depends on a seed phase that cannot be controlled experimentally. Nevertheless, it is natural to expect that among all possible hexagons on the ring the most unstable one will be the hexagon having nearest the zero value of ψ . It gives the minimal value of the threshold:

$$|B_k^{\text{minthresh}}|^2 = \frac{1}{16|C|^2}. \quad (9)$$

The numerical investigation of the boundary-value problem [Eqs. (3) and (4)] allows us to establish that for $|B_k^{\text{seed}}|^2 \leq |B_k^{\text{thresh}}|^2$ the solution with the positive sign before \sqrt{D} in Eq. (6) is unstable but the solution

with the negative sign is stable. Thus if in accordance with the experiment the space-charge amplitude $E_{2k_0, k}$ is zero for $t = 0$, the system tends to the stable weakly nonlinear solution [Eq. (6)] that corresponds to the low plateau (curve 1 in Fig. 3). But, if $|B_k^{\text{seed}}|^2 > |B_k^{\text{thresh}}|^2$, spontaneous hexagon formation takes place, and the power tends to the upper plateau (curve 2 in Fig. 3). This upper plateau corresponds to the strong nonlinear solution in which the intensity of the generated wave is of the order of the pump intensity (see, e.g., Ref. 8). Detailed consideration of this solution is beyond the scope of this Letter.

Note that spontaneous hexagon formation in our scheme is essentially a three-dimensional effect. There is no spontaneous generation of any transverse structures in one transverse dimension because in such a case the nonlinear terms in Eqs. (3) would be zero.

In the experiment we determined the threshold of spontaneous hexagon formation by changing the reflection coefficient or by changing γ . The typical experimental values of system parameters are $\gamma_r \approx 0$, $\gamma_i l \approx 3.2$, $k_d l \approx \pi$, $\exp(-2\alpha l) \approx 0.54$, and $|r|^2 \approx 0.6$. Then it follows from Eq. (9) that $|B_k^{\text{minthresh}}|^2 \approx 1.6 \times 10^{-6}$, in agreement with experiment.
